BACKGROUND OF THE INVENTION

1. Field of the Invention

This invention relates in general to the field of microelectronics, and more particularly to apparatus and methods for providing compressed configuration data in a fuse array associated with a multi-core device.

2. Description of the Related Art

Integrated device technologies have exponentially advanced over the past 40 years. More specifically directed to the microprocessor fields, starting with 4-bit, single instruction, 10-micrometer devices, the advances in semiconductor fabrication technologies have enabled designers to provide increasingly more complex devices in terms of architecture and density. In the 80's and 90's so-called pipeline microprocessors and superscalar microprocessors were developed comprising millions of transistors on a single die. And now 20 years later, 64-bit, 32-nanometer devices are being produced that have billions of transistors on a single die and which comprise multiple microprocessor cores for the processing of data.

One requirement that has persisted since these early devices were produced is the need to initialize these devices

2

with configuration data when they are turned on or when they are reset. For example, many architectures enable devices to be configured to execute at one of many selectable frequencies and/or voltages. Other architectures require that each device have a serial number and other information that can be read via execution of an instruction. Yet other devices require initialization data for internal registers and control circuits. Still other devices utilize configuration data to implement redundant circuits when primary circuits are fabricated in error or outside of marginal constraints.

As one skilled in the art will appreciate, designers have traditionally employed semiconductor fuse arrays on-die to store and provide initial configuration data. These fuse arrays are generally programmed by blowing selected fuses therein after a part has been fabricated and the arrays contain thousands of bits of information which is read by its corresponding device upon power-up/reset to initialize and configure the device for operation.

As device complexity has increase over the past years, the amount of configuration data that is required for a typical device has proportionately increased. Yet, as one skilled in the art will appreciate, though transistor size shrinks in proportion to the semiconductor fabrication process employed, semiconductor fuse size increases to the unique requirements for programming fuses on die. This phenomenon, in and of itself, is a problem for designers, who are prevalently constrained by real estate and power considerations. That is, there is just not enough real estate on a given die to fabricate a huge fuse array.

In addition, the ability to fabricate multiple device cores on a single die has geometrically exacerbated the problem, because configuration requirements for each of the cores results in requirement for a number of fuses on die, in a single array or distinct arrays, that are equal to the number of cores disposed thereon.

Therefore, what is needed is apparatus and methods that enable configuration data to be stored and provided to a multi-core device that require significantly less real estate and power on a single die than that which has heretofore been provided.

In addition, what is needed is a fuse array mechanism that can store and provide significantly more configuration data than current techniques while requiring the same or less real estate on a multi-core die.

SUMMARY OF THE INVENTION

The present invention, among other applications, is directed to solving the above-noted problems and addresses other problems, disadvantages, and limitations of the prior art by providing a superior technique for utilizing compressed configuration data in a fuse array associated with a multi-core device. In one embodiment, an apparatus is contemplated for providing configuration data to an integrated circuit. The apparatus has a semiconductor fuse array, a cache memory, and a plurality of cores. The semiconductor fuse array is disposed on a die, into which is programmed the configuration data. The semiconductor fuse array includes a first plurality of semiconductor fuses and a second plurality of semiconductor fuses. The first plurality of semiconductor fuses is configured to store compressed cache correction data. The second plurality of semiconductor fuses is configured to store compressed fuse correction data that indicates locations and values corresponding to one or more fuses within the first plurality of fuses whose states are to be changed from that which was previously stored. The cache memory is disposed on the die. The plurality of cores is disposed on the die, where

3

each of the plurality of cores is coupled to the semiconductor fuse array and the cache memory, and is configured to access the semiconductor fuse array upon power-up/reset. The each of the plurality of cores includes a cache fuses decompressor that is configured to change the states according to the locations and the values, to decompress the compressed cache correction data, and to distribute decompressed cached correction data to initialize the cache memory.

One aspect of the present invention contemplates an apparatus for reprogramming an integrated circuit device. The apparatus includes a multi-core microprocessor. The multi-core microprocessor includes a semiconductor fuse array, a cache memory, and a plurality of cores. The semiconductor fuse array is disposed on a die, into which is programmed the configuration data. The semiconductor fuse array includes a first plurality of semiconductor fuses and a second plurality of semiconductor fuses. The first plurality of semiconductor fuses is configured to store compressed cache correction data. The second plurality of semiconductor fuses is configured to store compressed fuse correction data that indicates locations and values corresponding to one or more fuses within the first plurality of fuses whose states are to be changed from that which was previously stored. The cache memory is disposed on the die. The plurality of cores is disposed on the die, where each of the plurality of cores is coupled to the semiconductor fuse array and the cache memory, and is configured to access the semiconductor fuse array upon power-up/reset. The each of the plurality of cores includes a cache fuses decompressor that is configured to change the states according to the locations and the values, to decompress the compressed cache correction data, and to distribute decompressed cached correction data to initialize the cache memory.

Another aspect of the present invention comprehends a method for reprogramming an integrated circuit. The method includes first disposing a semiconductor fuse array on a die. The first disposing includes first storing compressed cache correction data in a first plurality of semiconductor fuses; and second storing fuse correction data in a second plurality of semiconductor fuses, where the fuse correction data indicates locations and values corresponding to one or more fuses within the first plurality of fuses whose states are to be changed from that which was previously stored. The method also includes second disposing a plurality of microprocessor cores on the die, where each of the plurality of microprocessor cores is coupled to the shared fuse array and is configured to access all of the compressed configuration data during power-up/reset, for initialization of elements within the each of the plurality of cores. The method further includes, via a cache fuses decompressor disposed within the each of the plurality of cores, changing the states according to the locations and the values, decompressing the compressed cache correction data, and distributing decompressed cached correction data to initialize a cache memory.

Regarding industrial applicability, the present invention is implemented within a MICROPROCESSOR which may be used in a general purpose or special purpose computing device.

BRIEF DESCRIPTION OF THE DRAWINGS

These and other objects, features, and advantages of the present invention will become better understood with regard to the following description, and accompanying drawings where:

FIG. 1 is a block diagram illustrating a present day microprocessor core that includes a fuse array for providing configuration data to the microprocessor core;

4

FIG. 2 is a block diagram depicting a fuse array within the microprocessor core of FIG. 1 which includes redundant fuse banks that may be blown subsequent to blowing first fuse banks within the fuse array;

FIG. 3 is a block diagram featuring a system according to the present invention that provides for compression and decompression of configuration data for a multi-core device;

FIG. 4 is a block diagram showing a fuse decompression mechanism according to the present invention;

FIG. 5 is a block diagram illustrating an exemplary format for compressed configuration data according to the present invention;

FIG. 6 is a block diagram illustrating an exemplary format for decompressed microcode patch configuration data according to the present invention;

FIG. 7 is a block diagram depicting an exemplary format for decompressed microcode register configuration data according to the present invention;

FIG. 8 is a block diagram featuring an exemplary format for decompressed cache correction data according to the present invention;

FIG. 9 is a block diagram showing an exemplary format for decompressed fuse correction data according to the present invention;

FIG. 10 is a block diagram illustrating configurable redundant fuse arrays in a multi-core device according to the present invention;

FIG. 11 is a block diagram detailing a mechanism according to the present invention for rapidly loading configuration data into a multi-core device; and

FIG. 12 is a block diagram showing an error checking and correction mechanism according to the present invention.

DETAILED DESCRIPTION

Exemplary and illustrative embodiments of the invention are described below. In the interest of clarity, not all features of an actual implementation are described in this specification, for those skilled in the art will appreciate that in the development of any such actual embodiment, numerous implementation specific decisions are made to achieve specific goals, such as compliance with system-related and business related constraints, which vary from one implementation to the next. Furthermore, it will be appreciated that such a development effort might be complex and time-consuming, but would nevertheless be a routine undertaking for those of ordinary skill in the art having the benefit of this disclosure. Various modifications to the preferred embodiment will be apparent to those skilled in the art, and the general principles defined herein may be applied to other embodiments. Therefore, the present invention is not intended to be limited to the particular embodiments shown and described herein, but is to be accorded the widest scope consistent with the principles and novel features herein disclosed.

The present invention will now be described with reference to the attached figures. Various structures, systems, and devices are schematically depicted in the drawings for purposes of explanation only and so as to not obscure the present invention with details that are well known to those skilled in the art. Nevertheless, the attached drawings are included to describe and explain illustrative examples of the present invention. The words and phrases used herein should be understood and interpreted to have a meaning consistent with the understanding of those words and phrases by those skilled in the relevant art. No special definition of a term or phrase (i.e., a definition that is different from the ordinary and customary meaning as understood by those skilled in the art) is

intended to be implied by consistent usage of the term or phrase herein. To the extent that a term or phrase is intended to have a special meaning (i.e., a meaning other than that understood by skilled artisans) such a special definition will be expressly set forth in the specification in a definitional manner that directly and unequivocally provides the special definition for the term or phrase.

In view of the above background discussion on device fuse arrays and associated techniques employed within present day integrated circuits for providing configuration data during initial power-up, a discussion of the limitations and disadvantages of those techniques will be presented with reference to FIGS. 1-2. Following this, a discussion of the present invention will be presented with reference to FIGS. 3-12. The present invention overcomes all of the limitations and disadvantages discussed below by providing apparatus and methods for employing compressed configuration in a multi-core die which utilize less power and real estate on the multi-core die, and which are more reliable than that which has heretofore been provided.

DEFINITIONS

Integrated Circuit (IC): A set of electronic circuits fabricated on a small piece of semiconductor material, typically silicon. An IC is also referred to as a chip, a microchip, or a die.

Central Processing Unit (CPU): The electronic circuits (i.e., “hardware”) that execute the instructions of a computer program (also known as a “computer application” or “application”) by performing operations on data that include arithmetic operations, logical operations, and input/output operations.

Microprocessor: An electronic device that functions as a CPU on a single integrated circuit. A microprocessor receives digital data as input, processes the data according to instructions fetched from a memory (either on-die or off-die), and generates results of operations prescribed by the instructions as output. A general purpose microprocessor may be employed in a desktop, mobile, or tablet computer, and is employed for uses such as computation, text editing, multimedia display, and Internet browsing. A microprocessor may also be disposed in an embedded system to control a wide variety of devices including appliances, mobile telephones, smart phones, and industrial control devices.

Multi-Core Processor: Also known as a multi-core microprocessor, a multi-core processor is a microprocessor having multiple CPUs (“cores”) fabricated on a single integrated circuit.

Instruction Set Architecture (ISA) or Instruction Set: A part of a computer architecture related to programming that includes data types, instructions, registers, addressing modes, memory architecture, interrupt and exception handling, and input/output. An ISA includes a specification of the set of opcodes (i.e., machine language instructions), and the native commands implemented by a particular CPU.

x86-Compatible Microprocessor: A microprocessor capable of executing computer applications that are programmed according to the x86 ISA.

Microcode: A term employed to refer to a plurality of micro instructions. A micro instruction (also referred to as a “native instruction”) is an instruction at the level that a microprocessor sub-unit executes. Exemplary sub-units include integer units, floating point units, MMX units, and load/store units. For example, micro instructions are directly executed by a reduced instruction set computer (RISC) microprocessor. For a complex instruction set computer (CISC) microprocessor

such as an x86-compatible microprocessor, x86 instructions are translated into associated micro instructions, and the associated micro instructions are directly executed by a sub-unit or sub-units within the CISC microprocessor.

Fuse: A conductive structure typically arranged as a filament which can be broken at select locations by applying a voltage across the filament and/or current through the filament. Fuses may be deposited at specified areas across a die topography using well known fabrication techniques to produce filaments at all potential programmable areas. A fuse structure is blown (or unblown) subsequent to fabrication to provide for desired programmability of a corresponding device disposed on the die.

Turning to FIG. 1, a block diagram 100 is presented illustrating a present day microprocessor core 101 that includes a fuse array 102 for providing configuration data to the microprocessor core 101. The fuse array 102 comprises a plurality of semiconductor fuses (not shown) typically arranged in groups known as banks. The fuse array 102 is coupled to reset logic 103 that includes both reset circuits 104 and reset microcode 105. The reset logic 103 is coupled to control circuits 107, microcode registers 108, microcode patches elements 109, and cache correction elements 110. An external reset signal RESET is coupled to the microprocessor core 101 and is routed to the reset logic 103.

As one skilled in the art will appreciate, fuses (also called “links” or “fuse structures”) are employed in a vast number of present day integrated circuit devices to provide for configuration of the devices after the devices have been fabricated. For example, consider that the microprocessor core 101 of FIG. 1 is fabricated to provide functionality selectively either as a desktop device or a mobile device. Accordingly, following fabrication, prescribed fuses within the fuse array 102 may be blown to configure the device as, say, a mobile device. Accordingly, upon assertion of RESET, the reset logic 103 reads the state of the prescribed fuses in the fuse array 102 and the reset circuits 104 (rather than reset microcode 105, in this example) enable corresponding control circuits 107 that deactivate elements of microprocessor core 101 exclusively associated with desktop operations and activate elements of microprocessor core 101 exclusively associated with mobile operations. Consequently, microprocessor core 101 is configured upon power-up reset as a mobile device. In addition, the reset logic 103 reads the state of the other fuses in the fuse array 102 and the reset circuits 104 (rather than reset microcode 105, in this example) enable corresponding cache correction circuits 107 provide corrective mechanisms for one or more cache memories associated (not shown) with microprocessor core 101. Consequently, microprocessor core 101 is configured upon power-up reset as a mobile device and corrective mechanisms for its cache memories are in place.

The above example is merely one of many different uses for configuration fuses in an integrated circuit device such as a microprocessor core 101 of FIG. 1. One skilled in the art will appreciate that other uses for configuration fuses include, but are not limited to, configuration of device specific data (e.g., serial numbers, unique cryptographic keys, architecture mandated data that can be accessed by users, speed settings, voltage settings), initialization data, and patch data. For example, many present day devices execute microcode and often require initialization of microcode registers 108 that are read by the microcode. Such initialization data may be provided by microcode register fuses (not shown) within the fuse array 102, which are read upon reset and provided to the microcode registers 108 by the reset logic 103 (using either the reset circuits 104, the reset microcode 105, or both elements 104-105). For purposes of the present application, the

reset circuits **104** comprise hardware elements that provide certain types of configuration data, which cannot be provided via the execution of the reset microcode **105**. The reset microcode **105** comprises a plurality of micro instructions disposed within an internal microcode memory (not shown) that is executed upon reset of the microprocessor core **101** to perform functions corresponding to initialization of microprocessor core **101**, those functions including provision of configuration data that is read from the fuse array **102** to elements such as microcode registers **108** and microcode patch mechanisms **109**. The criteria for whether certain types of configuration data provided via fuses can be distributed to the various elements **107-110** in microprocessor core **101** via reset microcode **105** or not is a function primarily of the specific design of microprocessor core **101**. It is not the intent of the present application to provide a comprehensive tutorial on specific configuration techniques that are employed to initialize integrated circuit devices, for one skilled in the art will appreciate that for a present day microprocessor core **101** the types of configurable elements **107-110** generally fall into four categories as are exemplified in FIG. 1: control circuits, microcode registers, microcode patch mechanisms, and cache correction mechanisms. Furthermore, one skilled will appreciate that the specific values of the configuration data significantly vary based upon the specific type of data. For instance, a 64-bit control circuit **107** may include ASCII data that prescribes a serial number for the microprocessor core **101**. Another 64-bit control register may have 64 different speed settings, only one of which is asserted to specify an operating speed for the microprocessor core **101**. Microcode registers **108** may typically be initialized to all zeros (i.e. logic low states) or to all ones (i.e., logic high states). Microcode patch mechanisms **109** may include an approximately uniform distribution of ones and zeros to indicate addresses in a microcode ROM (not shown) along with replacement microcode values for those addresses. Finally, cache correction mechanisms may comprise very sparse settings of ones to indicate substitution control signals to replace a certain cache sub-bank element (i.e., a row or a column) with a particular replacement sub-bank element.

Fuse arrays **102** provide an excellent means for configuring a device such as a microprocessor core **101** subsequent to fabrication of the device. By blowing selected fuses in the fuse array **102**, the core can be configured for operation in its intended environment. Yet, as one skilled in the art will appreciate, operating environments may change following programming of the fuse array **102**. Business requirements may dictate that a microprocessor core **101** originally configured to support, say, a desktop computing device, be reconfigured to support an mobile computing device. Accordingly, designers have provided techniques that utilize redundant banks of fuses within the fuse array **102** to provide for “unblowing” selected fuses therein, thus enabling the microprocessor core **101** to be reconfigured, fabrication errors to be corrected, and etc. These redundant array techniques will now be discussed with reference to FIG. 2.

Referring now to FIG. 2, a block diagram **200** is presented depicting a fuse array **201** within the microprocessor core **101** of FIG. 1 including redundant fuse banks **202** RFB1-RFBN that that may be blown subsequent to blowing first fuse banks **202** PFB1-PFBN within the fuse array **201**. Each of the fuse banks **202** PFB1-PFBN, RFB1-RFBN comprises a prescribed number of individual fuses **203** corresponding to specific design of the microprocessor core **101**. For example, the number of fuses **203** in a given fuse bank **202** may be 64 fuses **203** in a 64-bit microprocessor core **101** to facilitate

provision of configuration data in a format that is easily implemented in the microprocessor core **101**.

The fuse array **201** is coupled to a set of registers **210-211** that are typically disposed within reset logic in the microprocessor core **101**. A primary register PR1 is employed to read one of the first fuse banks PFB1-PFBN (say, PFB3 as is shown in the diagram **200**) and a redundant register RR1 is employed to read a corresponding one of the redundant fuse banks RFB1-RFBN. The registers **210-211** are coupled to exclusive-OR logic **212** that generates an output FB3.

In operation, subsequent to fabrication of the microprocessor core **101**, the first fuse banks PFB1-PFBN are programmed by known techniques with configuration data for the microprocessor core **101**. The redundant fuse banks RFB1-RFBN are not blown and remain at a logic low state for all fuses therein. Upon power-up/reset of the microprocessor core **101**, both the first fuse banks PFB1-PFBN and the redundant fuse banks RFB1-RFBN are read as required for configuration into the primary and redundant registers **210-211**, respectively. The exclusive-OR logic **212** generates the output FB3 that is a logical exclusive-OR result of the contents of the registers **210-211**. Since all of the redundant fuse banks are unblown (i.e., logic low states), the output FB3 value is simply that which was programmed into the first fuse banks PFB1-PFBN subsequent to fabrication.

Consider now, though, that design or business requirements dictate that some of the information that was programmed into the first fuse banks PFB1-PFBN needs to change. Accordingly, a programming operation is performed to blow corresponding fuses **203** within the redundant fuse banks RFB1-RFBN in order to change the information that is read at power-up. By blowing a fuse **203** in a selected redundant bank RFB1-RFBN, the value of a corresponding fuse **203** in the primary fuse bank PFB1-PFBN is logically complemented.

The mechanism of FIG. 2 may be employed to provide for “reblow” of fuses **203** within a device, as alluded to above, but as one skilled in the art will appreciate, a given fuse **203** may only be reblown one time as there is only one set of redundant fuse banks RFB1-RFBN. To provide for additional reblows, a corresponding number of additional fuse banks **202** and registers **210-211** must be added to the microprocessor core **101**.

Heretofore, the fuse array mechanisms as discussed above with reference to FIGS. 1-2 has provided enough flexibility to sufficiently configure microprocessor cores and other related devices, while also allowing for a limited number of reblows. This is primarily due to the fact that former fabrication technologies, say 65 nanometer and 45 nanometer processes, allow ample real estate on a die for the implementation of enough fuses to provide for configuration of a core **101** disposed on the die. However, the present inventors have observed that present day techniques are limited going forward due to two significant factors. First, the trend in the art is to dispose multiple device cores **101** on a single die to increase processing performance. These so-called multi-core devices may include, say, 2-16 individual cores **101**, each of which must be configured with fuse data upon power-up/reset. Accordingly, for a 4-core device, four fuse arrays **201** are required in that some of the data associated with individual cores may vary (e.g., cache correction data, redundant fuse data, etc.). Secondly, as one skilled in the art will appreciate, as fabrication process technologies shrink to, say, 32 nanometers, while transistor size shrinks accordingly, fuse size increases, thus requiring more die real estate to implement the same size fuse array on a 32-nanometer die opposed to that on a 45-nanometer die.

Both of the above limitations, and others, pose significant challenges to device designers, and more specifically to multi-core device designers, and the present inventors note that significant improvements over conventional device configuration mechanisms can be implemented in accordance with the present invention, which allows for programming of individual cores in a multi-core device along with substantial increases in cache correction and fuse reprogramming ("re-blow") elements. The present invention will now be discussed with reference to FIGS. 3-12.

Turning to FIG. 3, a block diagram is presented featuring a system 300 according to the present invention that provides for compression and decompression of configuration data for a multi-core device. The multi-core device comprises a plurality of cores 332 disposed on a die 330 (aka, "a chip") which, as one skilled in the art will appreciate, comprises a small block of semiconducting material, on which a given functional circuit is fabricated. For illustrative purposes, four cores 332 CORE 1-CORE 4 are depicted on the die 330, although the present invention contemplates various numbers of cores 332 disposed on the die 330. In one embodiment, all the cores 332 share a single cache memory 334 that is also disposed on the die 330. A single programmable fuse array 336 is also disposed on the die 330 and each of the cores 332 are configured to access the programmable fuse array 336 to retrieve and decompress configuration data as described above during power-up/reset. Henceforth, the die 330 with the cores 332, cache memory 334, and programmable fuse array 336 disposed thereon will be referred to as a multi-core microprocessor 330.

In one embodiment, the cores 332 comprise microprocessor cores configured as the multi-core microprocessor 330. In another embodiment, the multi-core microprocessor 330 is configured as an x86-compatible multi-core microprocessor. In yet another embodiment, the cache 334 comprises a level 2 (L2) cache 334 associated with the microprocessor cores 332. In one embodiment, the programmable fuse array 336 comprises 8192 (8K) individual fuses (not shown), although other numbers of fuses are contemplated. In a single-core embodiment, only one core 332 is disposed on the die 330 and the core 332 is coupled to the cache 334 and programmable fuse array 336. The present inventors note that although features and functions of the present invention will henceforth be discussed in the context of a multi-core microprocessor 330, these features and functions are equally applicable to a single-core embodiment as well.

The system 300 also includes a device programmer 310 that includes a compressor 320 that is coupled to a virtual fuse array 303. In one embodiment, the device programmer 310 may comprise a CPU (not shown) that is configured to process configuration data and to program the programmable fuse array 336 following fabrication of the die 330 according to well known programming techniques. The CPU may be integrated into a wafer test apparatus that is employed to test the device die 330 following fabrication. In one embodiment, the compressor 320 may comprise an application program that executes on the device programmer 310 and the virtual fuse array 303 may comprise locations within a memory that is accessed by the compressor 320. The virtual fuse array 303 includes a plurality of virtual fuse banks 301, that each comprise a plurality of virtual fuses 302. In one embodiment the virtual fuse array 303 comprises 128 virtual fuse banks 301 that each comprise 64 virtual fuses 302, resulting in a virtual fuse array 303 that is 8 Kb in size.

Operationally, configuration information for the multi-core microprocessor 330 is entered into the virtual fuse array 303 as part of the fabrication process, and as is described

above with reference to FIG. 1. Accordingly, the configuration information comprises control circuits configuration data, initialization data for microcode registers, microcode patch data, and cache correction data. Further, as described above, the distributions of values for associated with each of the data types is substantially different from type to type. The virtual fuse array 303 is a logical representation of a fuse array (not shown) that comprises configuration information for each of the microprocessor cores 332 on the die 330 and correction data for each of the caches 334 on the die 330.

After the information is entered into the virtual fuse array 303, the compressor 320 reads the state of the virtual fuses 302 in each of the virtual fuse banks 301 and compresses the information using distinct compression algorithms corresponding to each of the data types to render compressed use array data which will be programmed into the programmable fuse array 336. In one embodiment, system data for control circuits is not compressed, but rather is transferred without compression. To compress microcode register data, a microcode register data compression algorithm is employed that is effective for compressing data having a state distribution that corresponds to the microcode register data. To compress microcode patch data, a microcode patch data compression algorithm is employed that is effective for compressing data having a state distribution that corresponds to the microcode patch data. To compress cache correction data, a cache correction data compression algorithm is employed that is effective for compressing data having a state distribution that corresponds to the cache correction data.

The device programmer 310 then programs the uncompressed and compressed fuse array data into the programmable fuse array 336 on the die 330.

Upon power-up/reset, each of the cores 332 may access the programmable fuse array 336 to retrieve the uncompressed and compressed fuse array data, and reset circuits/microcode (not shown) disposed within each of the cores 332 distributes the uncompressed fuse array data, and decompresses the compressed fuse array data according to distinct decompression algorithms corresponding to each of the data types noted above to render values originally entered into the virtual fuse array 303. The reset circuits/microcode then enter the configuration information into control circuits (not shown), microcode registers (not shown), patch elements (not shown), and cache correction elements (not shown).

Advantageously, the fuse array compression system 300 according to the present invention enables device designers to employ substantially fewer numbers of fuses in programmable fuse array 336 over that which has heretofore been provided, and to utilize the compressed information programmed therein to configure a multi-core microprocessor 330 during power-up/reset.

Turning now to FIG. 4, a block diagram 400 is presented showing a fuse decompression mechanism according to the present invention. The decompression mechanism may be disposed within each of the microprocessor cores 332 of FIG. 3. For purposes of clearly teaching the present invention, only one core 420 is depicted in FIG. 4 and each of the cores 332 disposed on the die comprise substantially equivalent elements as the core 420 shown. A programmable fuse array 401 disposed on the die as described above is coupled to the core 420. The programmable fuse array 401 comprises compressed microcode patch fuses 403, compressed register fuses 404, compressed cache correction fuses 405, and compressed fuse correction fuses 406. The programmable fuse array 401 may also comprise uncompressed configuration data (not shown) such as system configuration data as discussed above and/or block error checking and correction (ECC) codes (not

11

shown). The inclusion of ECC features according to the present invention will be discussed in further detail below.

The microprocessor core **420** comprises a reset controller **417** that receives a reset signal RESET which is asserted upon power-up of the core **420** and in response to events that cause the core **420** to initiate a reset sequence of steps. The reset controller **417** includes a decompressor **421**. The decompressor **421** has a patch fuses element **408**, a register fuses element **409**, and a cache fuses element **410**. The decompressor also comprises a fuse correction element **411** that is coupled to the patch fuses element **408**, the register fuses element **409**, and the cache fuses element **410** via bus **412**. The patch fuses decompressor is coupled to microcode patch elements **414** in the core **420**. The register fuses element **409** is coupled to microcode registers **415** in the core **420**. And the cache fuses element **410** is coupled to cache correction elements **416** in the core **420**. In one embodiment, the cache correction elements **416** are disposed within an on-die L2 cache (not shown) that is shared by all the cores **420**, such as the cache **334** of FIG. 3. Another embodiment contemplates cache correction elements **416** disposed within an L1 cache (not shown) within the core **420**. A further embodiment considers cache correction elements **416** disposed to correct both the L2 and L1 caches described above.

In operation, upon assertion of RESET the reset controller **417** reads the states of the fuses **403-406** in the programmable fuse array **401** and distributes the states of the compressed fuses **403-406** to the decompressor **421**. After the fuse data has been read and distributed, the fuse correction element **411** of the decompressor **421** decompresses the compressed fuse correction fuses states to render data that indicates one or more fuse addresses in the programmable fuse array **401** whose states are to be changed from that which was previously programmed. The data may also include a value for each of the one or more fuse addresses. The one or more fuse addresses (and optional values) are routed via bus **412** to the elements **408-410** so that the states of corresponding fuses processed therein are changed prior to decompression of their corresponding compressed data.

In one embodiment, the patch fuses element **408** comprises microcode that operates to decompress the states of the compressed microcode patch fuses **403** according to a microcode patch decompression algorithm that corresponds the microcode patch compression algorithm described above with reference to FIG. 3. In one embodiment, the register fuses element **409** comprises microcode that operates to decompress the states of the compressed register fuses **404** according to a register fuses decompression algorithm that corresponds to the register fuses compression algorithm described above with reference to FIG. 3. In one embodiment, the cache fuses element **410** comprises microcode that operates to decompress the states of the compressed cache correction fuses **405** according to a cache correction fuses decompression algorithm that corresponds to the cache correction fuses compression algorithm described above with reference to FIG. 3. After each of the elements **408-410** change the states of any fuses whose addresses (and optional values) are provided via bus **412** from the fuse correction element **411**, their respective data is decompressed according to the corresponding algorithm employed. As will be described in further detail below, the present invention contemplates multiple "reblows" of any fuse address within the physical fuse array prior to the initiation of the decompression process executed by any of the decompressors **408-411**. In one embodiment bus **412** may comprise conventional microcode programming mechanisms that are employed to transfer data between respective routines therein. The present invention further contemplates a com-

12

prehensive decompressor **421** having capabilities to recognize and decompress configuration data based upon its specific type. Accordingly, the recited elements **408-411** within the decompressor **421** are presented in order to teach relevant aspects of the present invention, however, contemplated implementations of the present invention may not necessarily include distinct elements **408-411**, but rather a comprehensive decompressor **421** that provides functionality corresponding to each of the elements **408-411** discussed above.

In one embodiment, the reset controller **417** initiates execution of microcode within the patch fuses element **408** to decompress the states of the compressed microcode patch fuses **403**. The reset controller **417** also initiates execution of microcode within the register fuses element **409** to decompress the states of the compressed register fuses **404**. And the reset controller **417** further initiates execution of microcode within the cache fuses element **410** to decompress the states of the compressed cache correction fuses **405**. The microcode within the decompressor **421** also operates to change the states of any fuses addressed by fuse correction data provided by the compressed fuse correction fuses **406** prior to decompression of the compressed data.

The reset controller **417**, decompressor **421**, and elements **408-411** therein according to the present invention are configured to perform the functions and operations as discussed above. The reset controller **417**, decompressor **421**, and elements **408-411** therein may comprise logic, circuits, devices, or microcode, or a combination of logic, circuits, devices, or microcode, or equivalent elements that are employed to execute the functions and operations according to the present invention as noted. The elements employed to accomplish these operations and functions within the reset controller **417**, decompressor **421**, and elements **408-411** therein may be shared with other circuits, microcode, etc., that are employed to perform other functions and/or operations within the reset controller **417**, decompressor **421**, and elements **408-411** therein or with other elements within the core **420**.

After the states of the fuses **403-406** within the programmable fuse array **401** have been changed and decompressed, the states of the decompressed "virtual" fuses are then routed, as appropriate to the microcode patch elements **414**, the microcode registers **415**, and the cache correction elements **416**. Accordingly, the core **420** is configured for operation following completion of a reset sequence.

The present inventors note that the decompression functions discussed above need not necessarily be performed in a particular order during a reset sequence. For example, microcode patches may be decompressed following decompression of microcode registers initialization data. Likewise, the decompression functions may be performed in parallel or in an order suitable to satisfy design constraints.

Furthermore, the present inventors note that the implementations of the elements **408-411** need not necessarily be implemented in microcode versus hardware circuits, since in a typical microprocessor core **420** there exist elements of the core **420** which can more easily be initialized via hardware (such as a scan chain associated with a cache) as opposed to direct writes by microcode. Such implementation details are left up to designer judgment. However, the present inventors submit that the prior art teaches that cache correction fuses are conventionally read and entered into a cache correction scan chain by hardware circuits during reset prior to initiating the execution of microcode, and it is a feature of the present invention to implement the cache fuses decompressor **410** in microcode as opposed to hardware control circuits since a core's caches are generally not turned on until microcode runs. By utilizing microcode to implement the cache fuses

13

element 410, a more flexible and advantageous mechanisms is provided for entering cache correction data into a scan chain, and significant hardware is saved.

Now referring to FIG. 5, a block diagram is presented illustrating an exemplary format 500 for compressed configuration data 500 according to the present invention. The compressed configuration data 500 is compressed by the compressor 320 of FIG. 3 from data residing in the virtual fuse array 303 and is programmed (i.e., “blown”) into the programmable fuse array 336 of the multi-core microprocessor 330. During a reset sequence, as is described above, the compressed configuration data 500 is retrieved from the programmable fuse array 336 by each of the cores 332 and is decompressed and corrected by the elements 408-411 of the decompressor 421 within each of the cores 420. The decompressed and corrected configuration data is then provided to the various elements 413-416 within the core 420 to initialize the core 420 for operation.

The compressed configuration data 500 comprises one or more compressed data fields 502 for each of the configuration data types discussed above and are demarcated by end-of-type fields 503. Programming events (i.e., “blows”) are demarcated by an end-of-blow field 504. The compressed data fields 502 associated with each of the data types are encoded according to a compression algorithm that is optimized to minimize the number of bits (i.e., fuses) that are required to store the particular bit patterns associated with each of the data types. The number of fuses in the programmable fuse array 336 that make up each of compressed data fields 502 is a function of the compression algorithm that is employed for a particular data type. For example, consider a core that comprises sixty-four 64-bit microcode registers which must be initialized to, say, all ones or all zeros. An optimum compression algorithm may be employed to yield 64 compressed data fields 502 for that data type, where each of the compressed data fields 502 comprises initialization data for a particular microcode register where the compressed data fields 502 are prescribed in register number order (i.e., 1-64). And each of the compressed data fields 502 comprises a single fuse which is blown if a corresponding microcode register is initialized to all ones, and which is not blown if the corresponding microcode register is initialized to all zeros.

The elements 408-410 of the decompressor 421 in the core 420 are configured to utilize the end-of-type fields 503 to determine where their respective compressed data is located within the programmable fuse array 336 and the fuse correction decompressor 411 is configured to utilize the end-of-blow fields 504 to locate compressed fuse correction data that has been programmed (i.e., blown) subsequent to an initial programming event. It is a feature of the present invention to provide a substantial amount of spare fuses in the programmable fuse array 336 to allow for a significant number of subsequent programming events, as will be discussed in more detail below.

The exemplary compressed type format discussed above is presented to clearly teach aspects of the present invention that are associated with compression and decompression of configuration data. However, the manner in which specific type data is compressed, demarcated, and the number and types of data to be compressed within the fuse array 401 is not intended to be restricted to the example of FIG. 5. Other numbers, types, and formats are contemplated that allow for tailoring of the present invention to various devices and architectures extant in the art.

Turning now to FIG. 6, a block diagram is presented illustrating an exemplary format for decompressed microcode patch configuration data 600 according to the present inven-

14

tion. During a reset sequence, compressed microcode patch configuration data is read by each core 420 from the programmable fuse array 401. The compressed microcode patch configuration data is then corrected according to fuse correction data provided via bus 412. Then, the corrected compressed microcode patch configuration data is decompressed by the patch fuses decompressor 408. The result of the decompression process is the decompressed microcode patch configuration data 600. The data 600 comprises a plurality of decompressed data blocks 604 corresponding to the number of microcode patch elements 414 within the core 420 that require initialization data. Each decompressed data block 604 comprises a core address field 601, a microcode ROM address field 602, and a microcode patch data field 603. The sizes of the fields 601-603 are a function of the core architecture. As part of the decompression process, the patch fuses decompressor 408 creates a complete image of the target data required to initialize the microcode patch elements 414. Following decompression of the microcode patch configuration data 600, conventional distribution mechanisms may be employed to distribute the data 603 to respectively addressed core and microcode ROM substitution circuits/registers in the microcode patch elements 414.

Now turning to FIG. 7, a block diagram is presented depicting an exemplary format for decompressed microcode register configuration data 700 according to the present invention. During a reset sequence, compressed microcode register configuration data is read by each core 420 from the programmable fuse array 401. The compressed microcode register configuration data is then corrected according to fuse correction data provided via bus 412. Then, the corrected compressed microcode register configuration data is decompressed by the register fuses decompressor 409. The result of the decompression process is the decompressed microcode register configuration data 700. The data 700 comprises a plurality of decompressed data blocks 704 corresponding to the number of microcode registers 415 within the core 420 that require initialization data. Each decompressed data block 704 comprises a core address field 701, a microcode register address field 702, and a microcode register data field 703. The sizes of the fields 701-703 are a function of the core architecture. As part of the decompression process, the register fuses decompressor 409 creates a complete image of the target data required to initialize the microcode registers element 415. Following decompression of the microcode register configuration data 700, conventional distribution mechanisms may be employed to distribute the data 703 to respectively addressed core and microcode registers element 415.

Referring now to FIG. 8, a block diagram is presented featuring an exemplary format for decompressed cache correction data 800 according to the present invention. During a reset sequence, compressed cache correction data is read by each core 332 from the programmable fuse array 401. The compressed cache correction data is then corrected according to fuse correction data provided via bus 412. Then, the corrected compressed cache correction data is decompressed by the cache fuses decompressor 410. The result of the decompression process is the decompressed cache correction data 800. Various cache mechanisms may be employed in the multi-core processor 330 and the decompressed cache correction data 800 is presented in the context of a shared L2 cache 334, where all of the cores 332 may access a single cache 334, utilizing shared areas. Accordingly, the exemplary format is provided according to the noted architecture. The data 800 comprises a plurality of decompressed data blocks 804 corresponding to the number of cache correction elements 416 within the core 420 that require corrective data.

15

Each decompressed data block **804** comprises a sub-unit column address field **802** and a replacement column address field **803**. As one skilled in the art will appreciate, memory caches are fabricated with redundant columns (or rows) in sub-units of the caches to allow for a functional redundant column (or row) in a particular sub-unit to be substituted for a non-functional column (or row). Thus, the decompressed cache correction data **800** allows for substitution of functional columns (as shown in FIG. **8**) for non-functional columns. In addition, as one skilled in the art will concur, conventional fuse array mechanisms associated with cache correction include fuses associated with each sub-unit column that are blown when substitution is required by redundant sub-unit columns. Accordingly, because such a large number of fuses are required (to address all sub-units and columns therein), only a portion of the sub-units are typically covered, and then the resulting conventional cache correction fuses are very sparsely blown. And the present inventors note that it is a feature of the present invention to address and compress sub-unit column addresses and replacement column addresses only for those sub-unit columns that require replacement, thus minimizing the number of fuses that are required to implement cache correction data. Consequently, the present invention, as limited by physical fuse array size and the amount of additional configuration data that is programmed therein, provides the potential for expanding the number of sub-unit columns (or rows) in a cache **334** that can be corrected over that which has heretofore been provided. In the embodiment shown in FIG. **8**, it is noted that the associated cores **332** are configured such that only one of the cores **332** sharing the L2 cache **334** would access and provide the corrective data **802-803** to its respective cache correction elements **416**. The sizes of the fields **802-803** are a function of the core architecture. As part of the decompression process, the cache correction fuses decompressor **410** creates a complete image of the target data required to initialize the cache correction elements **416**. Following decompression of the cache correction data **800**, conventional distribution mechanisms in the responsible core **420** may be employed to distribute the data **802-803** to respectively addressed cache correction elements **416**.

Turning now to FIG. **9**, a block diagram is presented showing an exemplary format for decompressed fuse correction data **900** according to the present invention. As has been discussed above, during reset the fuse correction decompressor **411** accesses compressed fuse correction data **406** within the programmable fuse array **401**, decompresses the compressed fuse correction data, and supplies the resulting decompressed fuse correction data **900** to the other decompressors **408-410** within the core **420**. The decompressed fuse correction data comprises one or more end-of-blow fields **901** that indicate the end of successively programming events in the programmable fuse array **401**. If a subsequent programming event has occurred, a reblow field **902** is programmed to indicate that a following one or more fuse correction fields **903** indicate fuses within the programmable fuse array **401** that are to be reblown. Each of the fuse correction fields comprises an address of a specific fuse within the programmable fuse array **401** that is to be reblown along with a state (i.e., blown or unblown) for the specific fuse. Only those fuses that are to be reblown are provided in the fuse correction blocks fields **903**, and each group of fields **903** within a given reblow event is demarcated by an end-of-blow field **901**. If reblow field **902**, properly encoded, is present after a given end-of-blow field **901**, then subsequent one or more fuses may be configured reblown as indicated by corresponding fuse correction fields. Thus, the present invention provides

16

the capability for a substantial number of reblows for the same fuse, as limited by array size and other data provided therein.

The present inventors have also observed that the real estate and power gains associated with utilization of a shared physical fuse array within which compressed configuration data is stored presents opportunities for additional features disposed on a multi-core die. In addition, the present inventors have noted that, as one skilled in the art will appreciate, present day semiconductor fuse structures often suffer from several shortcomings, one of which is referred to as "grow-back." Growback is the reversal of the programming process such that a fuse will, after some time, reconnect after it has been blown, that is, it goes from a programmed (i.e., blown) state back to an unprogrammed (i.e., unblown) state.

To address growback, and other challenges, the present invention provides several advantages, one of which is provision of redundant, yet configurable, physical fuse arrays. Accordingly, a configurable, redundant fuse bank mechanism will now be presented with reference to FIG. **11**.

Referring to FIG. **10**, a block diagram is presented illustrating configurable, redundant fuse arrays **1001** in a multi-core device **1000** according to the present invention. The multi-core device **1000** includes a plurality of cores **1002** that are configured substantially as described above with reference to FIGS. **8-9**. In addition, each of the cores **1002** includes array control **1003** that is programmed with configuration data within a configuration data register **1004**. Each of the cores **1002** is coupled to the redundant fuse arrays **1001**.

For purposes of illustration, only four cores **1002** and two physical fuse arrays **1001** are shown, however the present inventors note that the novel and inventive concepts according to the present invention can be extended to a plurality of cores **1002** of any number and to more than two physical fuse arrays **1001**.

In operation, each of the cores **1002** receives configuration data within the configuration data register **1004** that indicates a specified configuration for the physical fuse arrays **1001**. In one embodiment, the arrays may be configured according to the value of the configuration data as an aggregate physical fuse array. That is, the size of the aggregate physical fuse array is equal to the sum of the sizes of the individual physical fuse arrays **1001**, and the aggregate physical fuse array may be employed to store substantially more configuration data than is provided for by a single one of the individual fuse arrays **1001**. Accordingly, the array control **1003** directs its corresponding core **1002** to read the physical fuse arrays **1001** as an aggregate physical fuse array. In another embodiment, to address growback, according to the value of the configuration data, the physical fuse arrays **1001** are configured as redundant fuse arrays that are programmed with the same configuration data, and the array control **1003** within each of the cores **1002** comprises elements that enable the contents of the two (or more) arrays to be logically OR-ed together so that if one or more of the blown fuses within a given array **1001** exhibits growback, at least one of its corresponding fuses in the remaining arrays **1001** will still be blown. In a fail-safe embodiment, according to the value of the configuration data, one or more of the physical fuse arrays **1001** may be selectively disabled, and the remaining arrays **1001** enabled for use in either an aggregate configuration or a logically OR-ed configuration. Accordingly, the array control **1003** in each of the cores **1002** will not access contents of the selectively disabled arrays **1001**, and will access the remaining arrays according to the configuration specified by the configuration data in the configuration data register **1004**.

17

The configuration data registers **1004** may be programmed by any of a number of well known means to include programmable fuses, external pin settings, JTAG programming, and the like.

In another aspect, the present inventors have noted that there may exist challenges when one or more physical fuse arrays are disposed on a single die that comprises multiple cores which access the arrays. More specifically, upon power-up/reset each core in a multi-core processor must read the physical fuse array in a serial fashion. That is, a first core reads the array, then a second core, then a third core, and so on. As one skilled in the art will appreciate, compared to other operations performed by the core, the reading of a fuse array is exceedingly time consuming and, thus, when multiple cores must read the same array, the time required to do so is roughly the time required for one core to read the array multiplied by the number of cores on the die. And as one skilled in the art will appreciate, semiconductor fuses degrade as they are read and there are lifetime limitations, according to fabrication process, for the reading of those fuses to obtain reliable results. Accordingly, another embodiment of the present invention is provided to 1) decrease the amount of time required for all cores to read a physical fuse array and 2) increase the overall lifetime of the fuse array by decreasing the number of accesses by the cores in a multi-core processor upon power-up/reset.

Attention is now directed to FIG. **11**, where a block diagram is presented detailing a mechanism according to the present invention for rapidly loading configuration data into a multi-core device **1100**. The device **1100** includes a plurality of cores **1102** that are configured substantially as described above with reference to FIGS. **3-10**. In addition, each of the cores **1102** includes array control **1103** that is programmed with load data within a load data register **1104**. Each of the cores **1102** are coupled to a physical fuse array **1101** that is configured as described above with reference to FIGS. **3-10**, and to a random access memory (RAM) **1105** that is disposed on the same die as the cores **1102**, but which is not disposed within any of the cores **1102**. Hence, the RAM **1105** is referred to as "uncore" RAM **1105**.

For purposes of illustration, only four cores **1102** and a single physical fuse array **1101** are shown, however the present inventors note that the novel and inventive concepts according to the present invention can be extended to a plurality of cores **1102** of any number and to a plurality of physical fuse arrays **1101**.

In operation, each of the cores **1102** receives load data within the load data register **1104** that indicates a specified load order for data corresponding to the physical fuse array **1101**. The value of contents of the load register **1104** designates one of the cores **1102** as a "master" core **1102**, and the remaining cores as "slave" cores **1102** having a load order associated therewith. Accordingly, upon power-up/reset, the array control **1103** directs the master core **1102** to read the contents of the physical fuse array **1101** and then to write the contents of the physical fuse array **1101** to the uncore RAM **1105**. If a plurality of physical fuse arrays **1101** are disposed on the die, then the uncore RAM **1105** is sized appropriately to store the contents of the plurality of arrays **1101**. After the master core **1102** has written the contents of the physical fuse array **1101** to the uncore RAM **1105**, then array control **1103** directs their corresponding slave cores **1102** to read the fuse array contents from the uncore RAM **1105** in the order specified by contents of the load data register **1104**.

The load data registers **1104** may be programmed by any of a number of well known means to include programmable fuses, external pin settings, JTAG programming, and the like.

18

It is also noted that the embodiment of FIG. **11** may be employed in conjunction with any of the embodiments of the configurable, redundant fuse array mechanism discussed above with reference to FIG. **10**.

Now referring to FIG. **12**, a block diagram **1200** is presented illustrating an error checking and correction (ECC) mechanism according to the present invention. The ECC mechanism may be employed in conjunction with any of the embodiments of the present invention described above with reference to FIGS. **3-11** and provides for another layer of robustness for the compression and decompression of configuration data. The diagram depicts a microprocessor core **1220** disposed on a die that is coupled to a physical fuse array **1201** comprising compressed configuration data blocks **1203** as is described above. In addition to the compressed configuration data blocks **1203**, the array **1201** includes ECC code blocks **1202** that each are associated with a corresponding one of the data blocks **1203**. In one embodiment, the data blocks **1203** are 64 bits (i.e., fuses) in size and the ECC code blocks **1202** are 8 bits in size. The core **1220** includes a reset controller **1222** that receives a reset signal RESET. The reset controller **1222** has an ECC element **1224** that is coupled to a decompressor **1226** via bus CDATA. The ECC element **1224** is coupled to the fuse array **1201** via an address bus ADDR, a data bus DATA, and a code bus CODE.

In operation, the physical fuse array **1201** is programmed with configuration data in the data blocks **1203** as is described above with reference to FIGS. **3-11**. The configuration data corresponding to a particular data type (e.g., microcode path data, microcode register data) is not required to be programmed within the boundaries of a given data block **1203**, but rather may span more than one data block **1203**. Furthermore, configuration data corresponding to two or more types of configuration data may be programmed into the same data block **1203**. In addition, the array **1201** is programmed with ECC codes in the ECC code blocks **1202** that each result from ECC generation for the data programmed into a corresponding data block **1203** according to one of a number of well known ECC mechanisms including, but not limited to, SECDED Hamming ECC, Chipkill ECC, and variations of forward error correction (FEC) codes. In one embodiment, the addresses associated with a given data block **1203** and its corresponding ECC code block **1202** are known. Thus, it is not required that the corresponding ECC code block **1202** be located adjacent to the given data block **1203**, as is depicted in FIG. **12**.

The decompressor **1226** is configured and functions substantially similar to the decompressor **421** described above with reference to FIG. **4**, and as allude to with reference to FIGS. **5-11**. Upon reset of the core **1220**, prior to execution of any of the decompression functions described above, the ECC element within the reset controller **1222** accesses the fuse array **1201** to obtain its contents. Addresses associated with given data blocks **1203** and ECC code blocks **1202** may be obtained via bus ADDR. Compressed configuration data within each of the data blocks **1203** may be obtained via bus DATA. And ECC codes for each of the ECC code blocks **1202** may be obtained via bus CODE. As the noted data, addresses, and codes are obtained, the ECC element **1224** operates to generate ECC checks for the data retrieved for each data block **1203** according to the ECC mechanism that was employed to generate the ECC code stored in the corresponding ECC code block **1202**. The ECC element **1224** also compares the ECC checks with corresponding ECC codes obtained from the array **1201** to produce ECC syndromes. The ECC element **1224** further decodes the ECC syndromes to determine if no error occurred, a correctable error occurred, or a non-correct-

19

able error occurred. The ECC element **1224** moreover operates to correct correctable errors. Correct and corrected data is then routed to the decompressor **1226** via bus CDATA for decompression as described above. Non-correctable data is also passed to the decompressor **1226** via bus CDATA along with an indication of such. If an operationally critical portion of the configuration data is determined to be non-correctable, the decompressor **1226** may cause the core **1220** to shut down or otherwise flag the error.

One embodiment contemplates that the ECC element **1224** comprises one or more microcode routines that are executed to perform the ECC functions noted above.

Portions of the present invention and corresponding detailed description are presented in terms of software, or algorithms and symbolic representations of operations on data bits within a computer memory. These descriptions and representations are the ones by which those of ordinary skill in the art effectively convey the substance of their work to others of ordinary skill in the art. An algorithm, as the term is used here, and as it is used generally, is conceived to be a self-consistent sequence of steps leading to a desired result. The steps are those requiring physical manipulations of physical quantities. Usually, though not necessarily, these quantities take the form of optical, electrical, or magnetic signals capable of being stored, transferred, combined, compared, and otherwise manipulated. It has proven convenient at times, principally for reasons of common usage, to refer to these signals as bits, values, elements, symbols, characters, terms, numbers, or the like.

It should be borne in mind, however, that all of these and similar terms are to be associated with the appropriate physical quantities and are merely convenient labels applied to these quantities. Unless specifically stated otherwise, or as is apparent from the discussion, terms such as “processing” or “computing” or “calculating” or “determining” or “displaying” or the like, refer to the action and processes of a computer system, a microprocessor, a central processing unit, or similar electronic computing device, that manipulates and transforms data represented as physical, electronic quantities within the computer system’s registers and memories into other data similarly represented as physical quantities within the computer system memories or registers or other such information storage, transmission or display devices.

Note also that the software implemented aspects of the invention are typically encoded on some form of program storage medium or implemented over some type of transmission medium. The program storage medium may be electronic (e.g., read only memory, flash read only memory, electrically programmable read only memory), random access memory magnetic (e.g., a floppy disk or a hard drive) or optical (e.g., a compact disk read only memory, or “CD ROM”), and may be read only or random access. Similarly, the transmission medium may be metal traces, twisted wire pairs, coaxial cable, optical fiber, or some other suitable transmission medium known to the art. The invention is not limited by these aspects of any given implementation.

The particular embodiments disclosed above are illustrative only, and those skilled in the art will appreciate that they can readily use the disclosed conception and specific embodiments as a basis for designing or modifying other structures for carrying out the same purposes of the present invention, and that various changes, substitutions and alterations can be made herein without departing from the scope of the invention as set forth by the appended claims.

What is claimed is:

1. An apparatus for providing configuration data to an integrated circuit, the apparatus comprising:

20

a semiconductor fuse array, disposed on a die, into which is programmed the configuration data, said semiconductor fuse array comprising:

a first plurality of semiconductor fuses, configured to store compressed cache correction data; and

a second plurality of semiconductor fuses, configured to store compressed fuse correction data that indicates locations and values corresponding to one or more fuses within said first plurality of semiconductor fuses whose states are to be changed from that which was previously stored;

a cache memory, disposed on said die; and

a plurality of cores, disposed on said die, wherein each of said plurality of cores is coupled to said semiconductor fuse array and said cache memory, and is configured to access said semiconductor fuse array upon power-up/reset, said each of said plurality of cores comprising: a cache fuses decompressor, configured to change said states according to said locations and said values, to decompress said compressed cache correction data, and to distribute decompressed cached correction data to initialize said cache memory.

2. The apparatus as recited in claim 1, wherein said cache fuses decompressor decompresses said compressed cache correction data by executing microcode during power-up/reset.

3. The apparatus as recited in claim 1, wherein said first plurality of semiconductor fuses comprises a third plurality of semiconductor fuses that indicate one or more sub-unit locations within said cache memory that are not to be employed during normal operation.

4. The apparatus as recited in claim 3, wherein said first plurality of semiconductor fuses further comprises a fourth plurality of semiconductor fuses that indicate one or more replacement sub-unit locations within said cache memory that are to be employed during normal operation in replacement of corresponding ones of said one or more sub-unit locations.

5. The apparatus as recited in claim 4, wherein said sub-unit locations and said replacement sub-unit locations comprise columns and redundant columns, respectively, within said cache memory.

6. The apparatus as recited in claim 4, wherein said sub-unit locations and said replacement sub-unit locations comprise rows and redundant rows, respectively, within said cache memory.

7. The apparatus as recited in claim 1, wherein the integrated circuit comprises an x86-compatible multi-core microprocessor.

8. An apparatus for reprogramming an integrated circuit device, the apparatus comprising:

a multi-core microprocessor, comprising:

a semiconductor fuse array, disposed on a die, into which is programmed the configuration data, said semiconductor fuse array comprising:

a first plurality of semiconductor fuses, configured to store compressed cache correction data; and

a second plurality of semiconductor fuses, configured to store compressed fuse correction data that indicates locations and values corresponding to one or more fuses within said first plurality of fuses whose states are to be changed from that which was previously stored;

a cache memory, disposed on said die; and

a plurality of cores, disposed on said die, wherein each of said plurality of cores is coupled to said semiconductor fuse array and said cache memory, and is config-

21

ured to access said semiconductor fuse array upon power-up/reset, said each of said plurality of cores comprising:

a cache fuses decompressor, configured to change said states according to said locations and said values, to decompress said compressed cache correction data, and to distribute decompressed cached correction data to initialize said cache memory.

9. The apparatus as recited in claim 8, wherein said cache fuses decompressor decompresses said compressed cache correction data by executing microcode during power-up/reset.

10. The apparatus as recited in claim 8, wherein said first plurality of semiconductor fuses comprises a third plurality of semiconductor fuses that indicates one or more sub-unit locations within said cache memory that are not to be employed during normal operation.

11. The apparatus as recited in claim 10, wherein said first plurality of semiconductor fuses further comprises a fourth plurality of semiconductor fuses that indicates one or more replacement sub-unit locations within said cache memory that are to be employed during normal operation in replacement of corresponding ones of said one or more sub-unit locations.

12. The apparatus as recited in claim 11, wherein said sub-unit locations and said replacement sub-unit locations comprise columns and redundant columns, respectively, within said cache memory.

13. The apparatus as recited in claim 11, wherein said sub-unit locations and said replacement sub-unit locations comprise rows and redundant rows, respectively, within said cache memory.

14. The apparatus as recited in claim 1, wherein said multi-core microprocessor comprises an x86-compatible multi-core microprocessor.

15. A method for reprogramming an integrated circuit, the method comprising:

first disposing a semiconductor fuse array on a die, the first disposing comprising:

first storing compressed cache correction data in a first plurality of semiconductor fuses; and

second storing fuse correction data in a second plurality of semiconductor fuses, wherein the fuse correction

22

data indicates locations and values corresponding to one or more fuses within the first plurality of semiconductor fuses whose states are to be changed from that which was previously stored;

second disposing a plurality of microprocessor cores on the die, wherein each of the plurality of microprocessor cores is coupled to the semiconductor fuse array and is configured to access all of the compressed cache correction data during power-up/reset, for initialization of elements within the each of the plurality of microprocessor cores; and

via a cache fuses decompressor disposed within the each of the plurality of cores, changing the states according to the locations and the values, decompressing the compressed cache correction data, and distributing decompressed cache correction data to initialize a cache memory.

16. The method as recited in claim 15, wherein the cache fuses decompressor decompresses the compressed cache correction data by executing microcode during power-up/reset.

17. The method as recited in claim 15, wherein the first plurality of semiconductor fuses comprises a third plurality of semiconductor fuses that indicates one or more sub-unit locations within the cache memory that are not to be employed during normal operation.

18. The method as recited in claim 17, wherein the first plurality of semiconductor fuses further comprises a fourth plurality of semiconductor fuses that indicates one or more replacement sub-unit locations within the cache memory that are to be employed during normal operation in replacement of corresponding ones of the one or more sub-unit locations.

19. The method as recited in claim 18, wherein the sub-unit locations and the replacement sub-unit locations comprise columns and redundant columns, respectively, within the cache memory.

20. The method as recited in claim 18, wherein the sub-unit locations and the replacement sub-unit locations comprise rows and redundant rows, respectively, within the cache memory.

21. The apparatus as recited in claim 15, wherein the integrated circuit comprises an x86-compatible multi-core microprocessor.
